A case of mumps complicated by meningo-encephalomyelitis and appendicitis

M N Lucas¹, S Dias²

(Key words: mumps, meningo-encephalomyelitis, appendicitis)

**Introduction**

Mumps is known to cause complications such as meningo-encephalomyelitis, orchitis, epidydimitis, oophoritis, pancreatitis, thyroiditis, myocarditis, deafness, ocular complications and arthritis¹,². It is known that mumps, complicated by right sided orchitis and oophoritis, is commonly mistaken for appendicitis¹,². However, it is less well known that mumps is listed as one of the risk factors as well as a causative virus for appendicitis³,⁴.

**Case report**

A 10 year old girl presented to ward 6B, General Hospital, Kalutara on 3rd August, 2006, with headache, fever and vomiting of one day duration. She had a severe frontal headache associated with neck pain. There was no photophobia. She had vomited 11 times, the vomitus containing food particles but no blood. Five days back, she had developed a left sided parotid swelling suggestive of mumps. There was a strong contact history with many of her classmates, too, having mumps. She had not been immunized with MMR vaccine.

On admission, she was ill looking, febrile and had neck stiffness. Kernigs sign was negative and her vital signs were stable. She had a slight swelling over the left parotid area. A presumptive diagnosis of meningitis was made and treatment instituted. Her investigation results were as follows: C-reactive protein <12 mg/l, white cell count 10.8x10⁹/l (N 78%, L 20%, E 2%), random blood sugar 87 mg/dl, CSF turbid, (protein 75 mg/dl, N 65, L 625, RBC 75, sugar 44 mg/dl, culture – no growth). Treatment was initiated with intravenous crystalline penicillin 2g 6 hourly and ceftriaxone 3.5 g daily on 4th August.

She complained of a vague abdominal pain on 7th August. There were no features of acute pancreatitis / oophoritis at the time. Ultrasound scan (USS) of the abdomen revealed no abnormality. However, her serum amylase was 1187 Somogyi units/l (normal range <300). On 8th August, she developed periumbilical colicky pain which shifted to the right iliac fossa (RIF). It was not associated with nausea or vomiting. Her fever, which was coming down gradually, started to spike again the same day. Bowel habits were normal and she did not have any urinary symptoms. RIF tenderness, maximal at McBurney point, was found. At this stage, the possibility of acute appendicitis was considered. The USS of abdomen was repeated and an echogenic mass, resembling an inflamed appendix, was seen. She was referred to the general surgeon who made a clinical diagnosis of acute appendicitis warranting immediate surgery. Appendicectomy was carried out on 8th August. A perforated, inflamed appendix, with minimal peritoneal contamination, was found. Intravenous metronidazole was added to the treatment regime and was given for 5 days. The antimeningitic treatment was continued for 14 days. She had an uneventful recovery and sat the year 5 scholarship examination 2 days before discharge. She was confirmed to have mumps IgM antibody by an enzyme immunoassay (EIA) test done at the Medical Research Institute.

**Discussion**

Mumps is a systemic illness caused by the paramyxovirus, transmitted by respiratory droplets. It has an incubation period of 14-25 days after which prodromal symptoms occur lasting for 3-5 days¹. After the prodrome, symptoms of the virus depend on the organ affected. The most common presentation is a parotitis occuring in 30-40% of patients¹. Other reported sites of infection are the testes, pancreas, eyes, ovaries, central nervous system, joints, and kidneys¹. A patient is considered infectious from about 3 days before onset up to 4 days into active parotitis. Infections can be asymptomatic in up to 20% of persons¹.

The clinical case-definition of mumps is an acute onset of unilateral or bilateral, tender, self-limited swelling of the parotid or other salivary gland lasting

¹Paediatric Registrar, ²Consultant Paediatrician, General Hospital, Kalutara.
for more than 2 days without other apparent cause. A lymphocytosis or leucopenia may be present. Serum amylase level may be elevated. CNS infections usually exhibit a lymphocytic pleocytosis.

Serology is the simplest method for confirming mumps virus infection and EIA is the most commonly used test being more sensitive than other serologic tests. It is available for both IgM and IgG. IgM antibodies usually become detectable during the first few days of illness and reach a peak about a week after onset. However, mumps IgM may be transient or missing in persons who have had any doses of mumps-containing vaccine. Sera should be collected as soon as possible after symptom onset for IgM testing or as the acute-phase specimen for IgG seroconversion. Convalescent-phase sera should be collected 2 weeks later.

Central nervous system (CNS) involvement is the form of meningo-encephalomyelitis is common, occurring asymptptomatically (inflammatory cells in cerebrospinal fluid) in 50%–60% of patients. Symptomatic meningo-encephalomyelitis (headache, stiff neck) occurs in up to 15% of patients and resolves without sequelae in 3–10 days. Boys are more commonly affected than girls (3:1 ratio). Parotitis may be absent in as many as 50% of such patients.

Orchitis is the most common complication in postpubertal males. It occurs in as many as 50% of postpubertal males, usually after parotitis, but may precede it, begin simultaneously, or occur alone. It is bilateral in approximately 30% of affected males. Approximately 50% of patients with orchitis have some degree of testicular atrophy, but sterility is rare. Oophoritis occurs in 5% of postpubertal females. It may mimic appendicitis. There is no relationship to impaired fertility.

Pancreatitis is infrequent, but occasionally occurs without parotitis; the hyperglycemia is transient and is reversible. Although single instances of diabetes mellitus have been reported, a causal relationship with mumps virus infection has yet to be conclusively demonstrated; many cases of temporal association have been described both in siblings and individuals, and outbreaks of diabetes have been reported a few months or years after outbreaks of mumps.

Deafness caused by mumps virus occurs in approximately 1 per 20,000 reported cases. Hearing loss is unilateral in approximately 80% of cases and may be associated with vestibular reactions. Onset is usually sudden and results in permanent hearing impairment. Electrocardiogram changes compatible with myocarditis are seen in 3–15% of patients with mumps, but symptomatic involvement is rare. Complete recovery is the rule, but deaths have been reported. Other less common complications of mumps include arthralgia, arthritis, and nephritis.

The relationship between mumps and appendicitis is little known. Mumps is stated both as a risk factor and as a virus in the aetiology of appendicitis.

Acknowledgement

We thank Dr Mahanama Gunasekera, Consultant Surgeon, General Hospital, Kalutara for performing surgery on this patient.
