Case Report

A case of Type 1 hereditary angio-oedema

G N Lucas¹, H Abeywickrema², B H S Premasiri³

(Key words: Type 1 hereditary angioedema)

Introduction

Hereditary angioedema (HAE) is associated with a deficiency of functionally active C 1 esterase inhibitor in serum leading to uncontrolled activation of the classical pathway of complement¹ with generation of vasoactive substances and subsequent manifestations of the characteristic clinical features²,³. This biochemical abnormality is inherited in an autosomal dominant manner and immunochemical studies have defined two principal forms of this condition⁴,⁵. The predominant form, hereditary angioedema (HAE) Type 1 is characterised by decreased levels of C 1-inhibitor protein on immunoassay and low functional C 1-inhibitor activity. Patients with hereditary angioedema (HAE) Type 2 have normal or elevated concentrations of C 1-inhibitor protein but synthesize functionally deficient C 1-inhibitor species⁴,⁵.

In 1969 an acquired form of C 1-inhibitor deficiency (AAE) was described by Constanzi et al⁶. In this rare condition the onset of symptoms is in middle age and there are nearly always associated underlying benign or malignant B-cell lymphoproliferative disorders⁷. Recently an autoantibody-mediated acquired deficiency of C 1-inhibitor has been described⁸.

Case report

A four and a half year old boy was admitted to Lady Ridgeway Hospital in October, 1999 with painless swellings of both knees, left ankle, both wrists, lower back and dorsa of hands. The child was afebrile and swellings were non pitting and non pruritic with no overlying erythema. There was no accompanying abdominal pain. There were 3 similar episodes during the previous 6 months. There was no family history of similar episodes. There was no consanguinity. The swellings gradually disappeared over the next few days.

¹Consultant Paediatrician, ²Paediatric Registrar, ³Senior House Officer, Lady Ridgeway Hospital, Colombo.

The total white cell count was 7.2 x 10⁹/L (N 61%, L 39%). Haemoglobin was 12.6g/dl. The ESR was 25 mm in the first hour. The C 1 Esterase Inhibitor level was 12.19 mg/dl (normal range 15 - 35 mg/dl).

The child was re-admitted to hospital in December, 1999 with similar painless non pruritic swellings. He was started on Tranexamic acid 250 mg twice a day and this was discontinued after one month. One month after discontinuing Tranexamic acid child was re-admitted to hospital with angioedema. He was restarted on Tranexamic acid and up to date he has had no more recurrences.

Discussion

Hereditary angioedema results from a genetic deficiency of the inhibitor of the first component of complement (C 1 esterase or C 1)¹. Mortality from this disease has been reported to be as high as 30%, death usually being caused by airway obstruction²,³. In acute, life-threatening attacks, replacement therapy with purified C 1 inhibitor is the treatment of choice²,⁹. Two classes of drugs can be used for the prophylaxis of attacks of hereditary angioedema. The antifibrinolytic agents such as epsilon aminocaproic acid and tranexamic acid have been shown to be effective¹⁰,¹¹. The second group of drugs are the androgens. Postpuberty, an attenuated androgen is the drug of choice. The most widely used attenuated androgens are danazol and stanozolol, the latter being less expensive and having less masculinizing side effects¹²,¹³. In our child tranexamic acid was used for prophylaxis.
